Homework 4 – Regression Consult

When people make decisions, their choices are often swayed by how information is presented. This is often described as "the framing effect." One example of this, is how commercials describe new medications. As an example, Nereus (tradipitant), a new drug for motion-induced vomiting like sea-sickness, is marketed with a **positive frame** as reducing vomiting incidence from 44% to 18% (a reduction of 60%). This marketing makes it seem more effective than a **negative frame** that says just 18% of patients still experienced vomiting, even though both statements are true.

Xu (2024) aimed to evaluate whether older adults are more or less vulnerable to framing than younger adults. They collected a sample of 696 adults aged 18 to 71 and exposed them to three different scenarios

Scenario 1: Rate Drug Efficacy (1 = very bad, 6 = very good)

- **Positive Frame:** 70 out of 100 patients felt better
- **Negative Frame:** 30 out of 100 patients did not feel better

Scenario 2: Likelihood to stop drinking cocoa (1 = surely stop, 6 = surely continue)

- **Positive Frame:** Stopping drinking hot cocoa reduces cadmium and cancer risk.
- **Negative Frame:** Continuing to drink hot cocoa increases cadmium and cancer risk.

Scenario 3: Preference for chance choice (1 = surely safe option, 6 = surely risky)

- **Positive Frame:** Choice between 200 saved vs 1/3 chance all 600 are saved.
- **Negative Frame:** Choice between 400 die vs 2/3 chance all 600 die.

In each scenario, participants were randomly assigned a positive or negative frame. They rated their response on a 1-6 scale. The researchers want to build three models, one for each scenario adjusting for simultaneous linear changes in demographic variables (gender, ethnicity, education level, political affiliation).

They want to evaluate whether, as adults age, the way choices are worded have more influence on their judgments and ultimate choices. If there is a change, are those changes driven by positive or negative framings? At what age does this effect onset?

Your Goals:

- Determine the correct analysis strategy and conduct the necessary analyses.
  - Hint 1: Ensure to assess and communicate results about the model fit.
  - Hint 2: Ensure to think about whether or which interactions need to be included.
  - Hint 3: You will need run various post hoc procedures (e.g., `emmeans`, `emtrends` or `johnson_neyman`).
  - Hint 4: Looking at the paper may be helpful. They do include `R` code, but I expect you to do a much better job using the techniques we discussed (they do somethings differently)
- Write a clear, concise, complete, and correct report conveying an answer to their research question.

The data are in `HW4Data.csv` but they will require some manual and `tidyverse` cleaning.

1 Loading and Cleaning the Data

```
dat.raw <- read_csv("HW4Data.csv", name_repair = "unique_quiet")
new.names <- unlist(dat.raw[1, ], use.names = FALSE)

dat <- dat.raw[-1, !is.na(new.names)]
names(dat) <- str_trim(new.names[!is.na(new.names)])
dat <- dat |>
```

```
  type_convert()

dim(dat)

The raw export had two header rows and 20 empty trailing columns; I kept the variable-name row as headers and dropped the empty columns. Of 842 rows, 696 were completed surveys. I kept only the 592 participants who passed both attention checks. I set the positive frame as the reference level, so the interaction term estimates how the age effect differs under the negative frame. I collapsed sparse demographic categories: gender (Female, Male, Other), ethnicity (White, Black, Asian, Other), education (High school or less, Some college, 2 year, 4 year, Graduate), and politics (Democrat, Republican, Independent, Other).

2 Exploratory Data Analyses

```r
dat |>
  group_by(frame1) |>
  summarize(n = n(), Mean = mean(pick1), SD = sd(pick1)) |>
  knitr::kable(digits = 3)
```

         40.88814          40.72054
```

```
t.test(age ~ frame3, data = dat)
```

```
    Welch Two Sample t-test

data:  age by frame3
t = -1.5555, df = 588.13, p-value = 0.1204
alternative hypothesis: true difference in means between group pos and group neg is not equal to 0
95 percent confidence interval:
 -3.6043605  0.4184115
sample estimates:
mean in group pos mean in group neg
         40.02640          41.61938
```

```r
GGally::ggpairs(dat, columns = c("age", "gender", "ethnicity", "education", "politics")) +
  theme_bw() +
  theme(axis.text.x = element_text(angle = 45, hjust = 1))
```

I first compared mean responses by frame. The drug was rated as more effective under the positive frame, participants were less willing to continue drinking cocoa under the negative frame, and they preferred the risky option more under the negative frame. Plotting responses against age by frame showed that the positive-frame lines were nearly flat, while the negative-frame lines changed with age, so the gap between frames appeared to widen for older adults; this suggests a frame × age interaction driven by the negative frame. Welch t-tests found no age difference between frames in any scenario, confirming that random assignment balanced age. Pairwise plots showed no clear associations among the predictors, so multicollinearity does not appear to be a concern.

3 Regression Analyses

3.1 Rating Drug Efficacy

```
source("plotResiduals.R")
source("plotInfluence.R")
```

```
mean.age <- mean(dat$age)

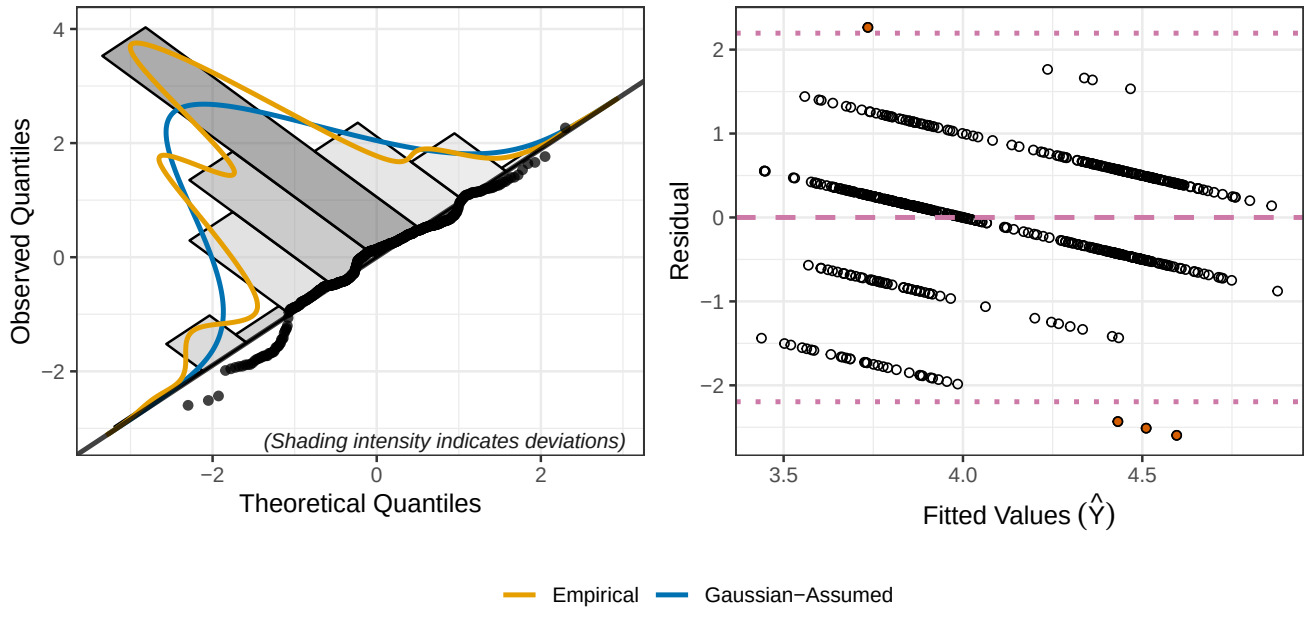

dat <- dat |>
  mutate(age.c = age - mean.age)

mean.age
```

```
[1] 40.80405
```

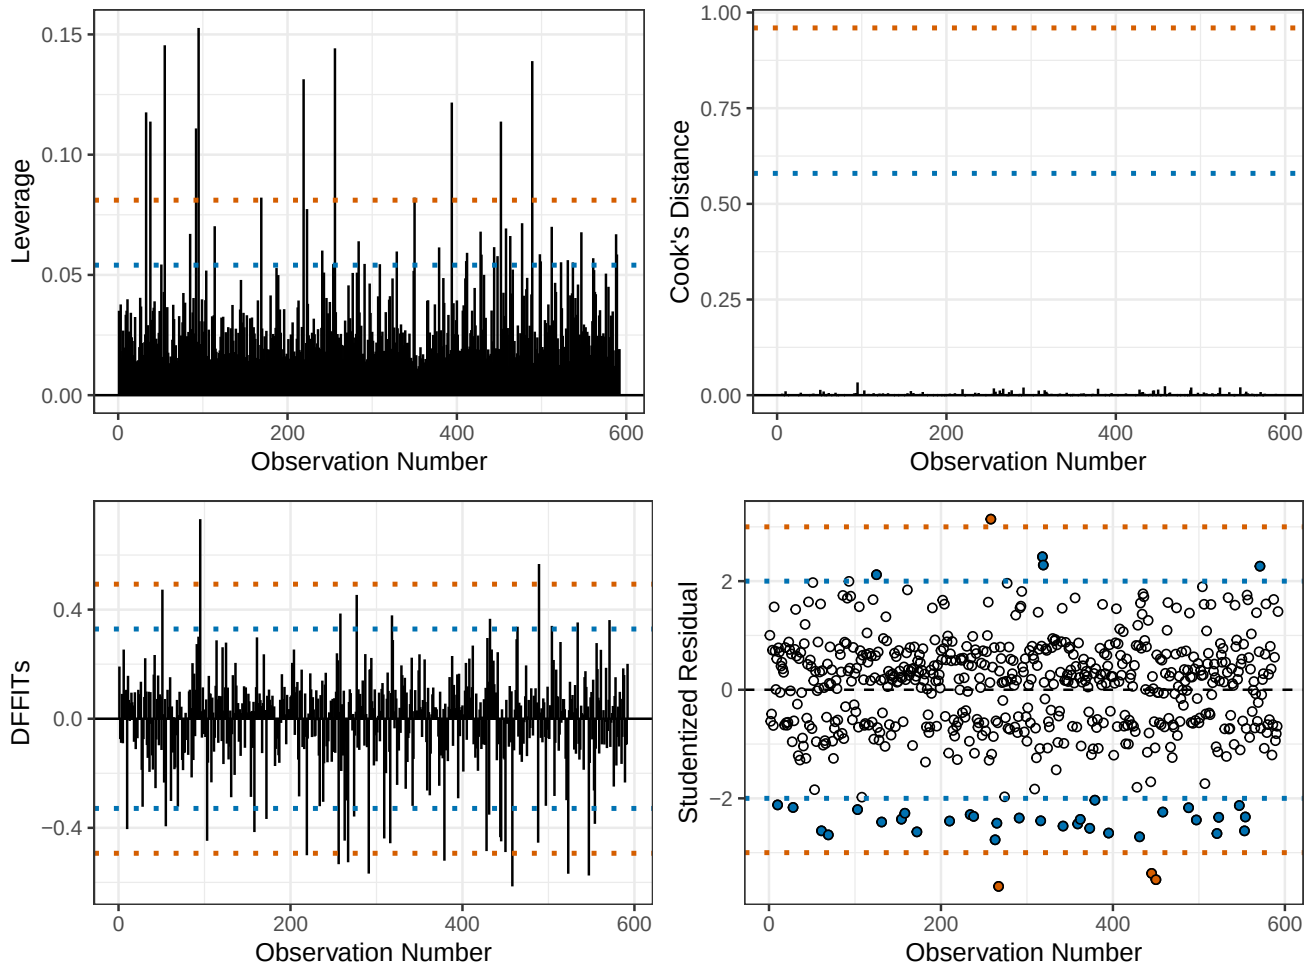

```
mod1 <- lm(pick1 ~ frame1 * age.c + gender + ethnicity + education + politics,
           data = dat)
```

```
plotResiduals(mod1)
```

The residuals fall along parallel bands because responses can only be integers from 1 to 6. The Q-Q plot shows that the residuals are close to Gaussian.

```
plotInfluence(mod1)
```

Several observations have high leverage, likely because they belong to small demographic groups. However, all Cook's distances are far below the moderate threshold, so no single observation has a strong influence on the model.

```
car::vif(mod1)
```

```
                GVIF Df GVIF^(1/(2*Df))
frame1      1.017894  1        1.008907
age.c       2.339811  1        1.529644
gender      1.075843  2        1.018444
ethnicity   1.143267  3        1.022566
education   1.133688  4        1.015808
politics    1.185533  3        1.028772
frame1:age.c 2.264757  1        1.504911
```

```
car::vif(lm(pick1 ~ frame1 + age.c + gender + ethnicity + education + politics,
            data = dat))
```

```
              GVIF Df GVIF^(1/(2*Df))
frame1    1.017889  1        1.008905
age.c     1.055095  1        1.027178
gender    1.073616  2        1.017917
ethnicity 1.137853  3        1.021757
education 1.130613  4        1.015463
politics  1.178447  3        1.027744
```

All adjusted GVIF values were between 1.0 and 1.5, so multicollinearity is not a concern.

Results are averaged over the levels of: gender, ethnicity, education, politics
```

Under the positive frame, ratings rose slightly with age, while under the negative frame they fell slightly with age. Neither slope was significant on its own, but the difference between them was. So the framing effect grows with age because of small opposing trends in both frames, not because of the negative frame alone.

```
ages <- c(20, 30, 40, 50, 60, 70)

emm.mod1 <- emmeans::emmeans(mod1, ~ frame1 | age.c,
                             at = list(age.c = ages - mean.age))

Results are averaged over the levels of: gender, ethnicity, education, politics
```

The framing effect (positive minus negative) increased steadily with age, from 0.44 points at age 20 to 0.94 points at age 70, and it was significant at every age I tested.

```
dat <- dat |>
  mutate(neg1 = as.numeric(frame1 == "neg"))

mod1.jn <- lm(pick1 ~ neg1 * age + gender + ethnicity + education + politics,
              data = dat)

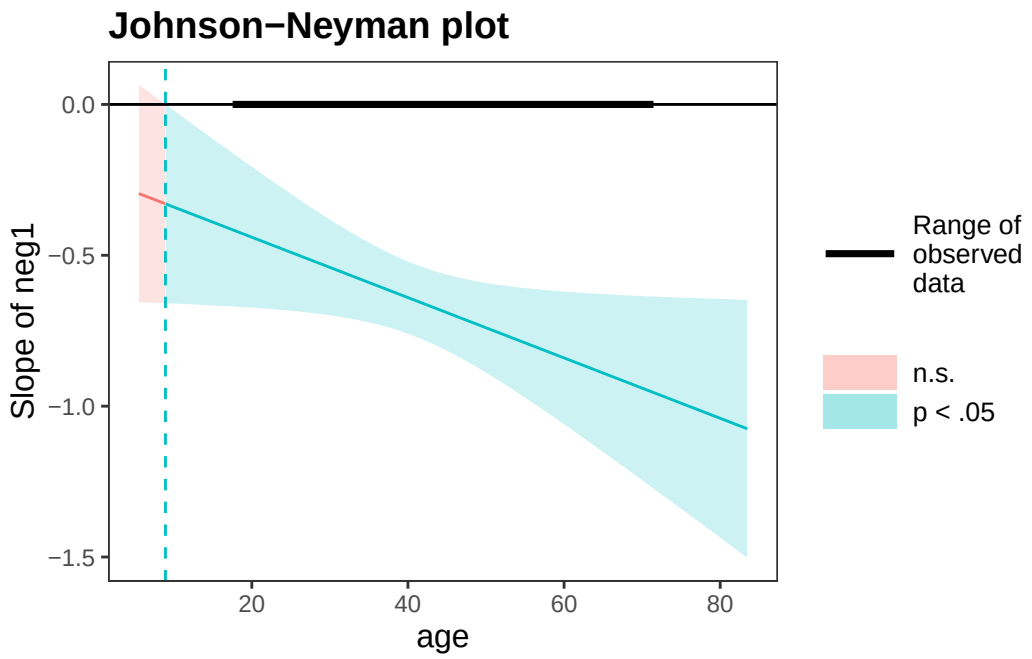

interactions::johnson_neyman(mod1.jn, pred = "neg1", modx = "age",
                             control.fdr = TRUE)
```

```
JOHNSON-NEYMAN INTERVAL

When age is OUTSIDE the interval [-1674.92, 8.94], the slope of neg1 is p <
.05.

Note: The range of observed values of age is [18.00, 71.00]

Interval calculated using false discovery rate adjusted t = 1.96
```

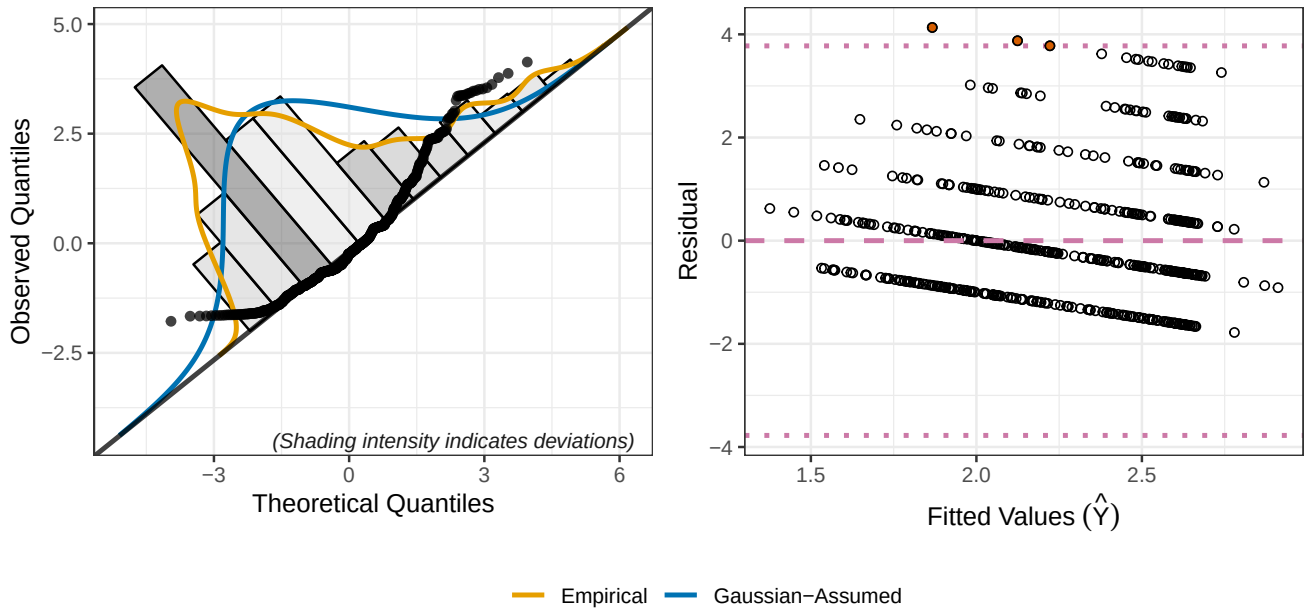

The Johnson-Neyman analysis showed that the framing effect is significant for all ages above 8.94. Since the youngest participant was 18, the framing effect was significant across the entire observed age range.

3.2 Likelihood to Stop Drinking Cocoa

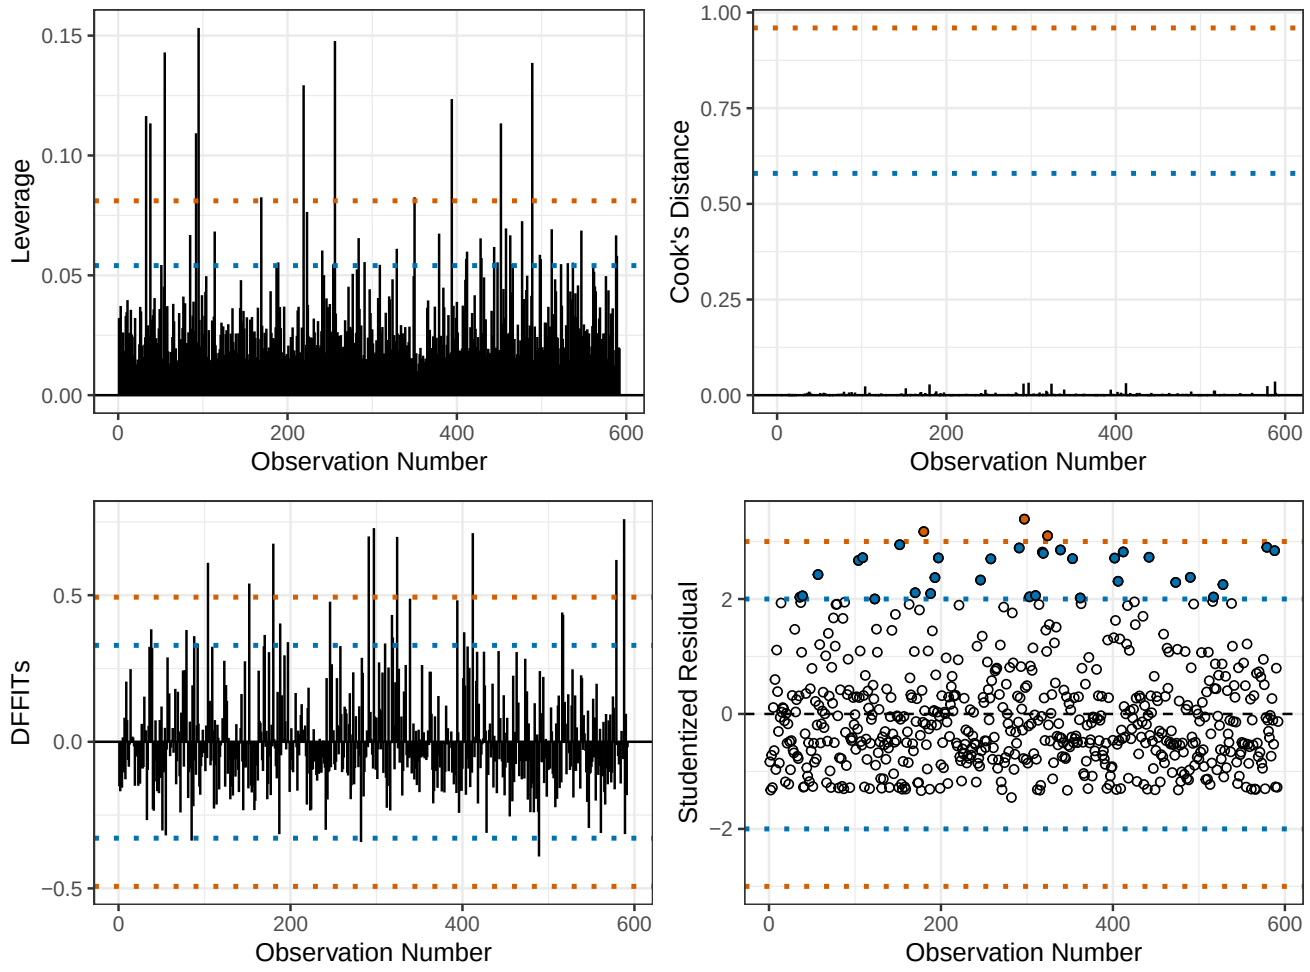

```
mod2 <- lm(pick2 ~ frame2 * age.c + gender + ethnicity + education + politics,
           data = dat)
```

```
plotResiduals(mod2)
```

The residuals again fall along parallel bands because responses are integers from 1 to 6. Residuals are right-skewed: the Q-Q plot shows a heavier upper tail than expected under a Gaussian distribution.

```
plotInfluence(mod2)
```

Some observations have high leverage, but all Cook's distances are far below the moderate threshold, so no observation is highly influential.

```
car::vif(mod2)
```

```
                GVIF Df GVIF^(1/(2*Df))
frame2      1.033200  1        1.016464
age.c       2.168475  1        1.472574

```
 pos - neg    0.852 0.267 576   3.188  0.0015

Results are averaged over the levels of: gender, ethnicity, education, politics
```

The estimated framing effect grew from 0.35 points at age 20 to 0.85 points at age 70. It was not significant at age 20 ($p = 0.084$) but was significant from age 30 onward. Because the interaction was not significant, this pattern mostly reflects larger standard errors at the youngest ages rather than a true change in the framing effect.

```
dat <- dat |>
  mutate(neg2 = as.numeric(frame2 == "neg"))

mod2.jn <- lm(pick2 ~ neg2 * age + gender + ethnicity + education + politics,
              data = dat)

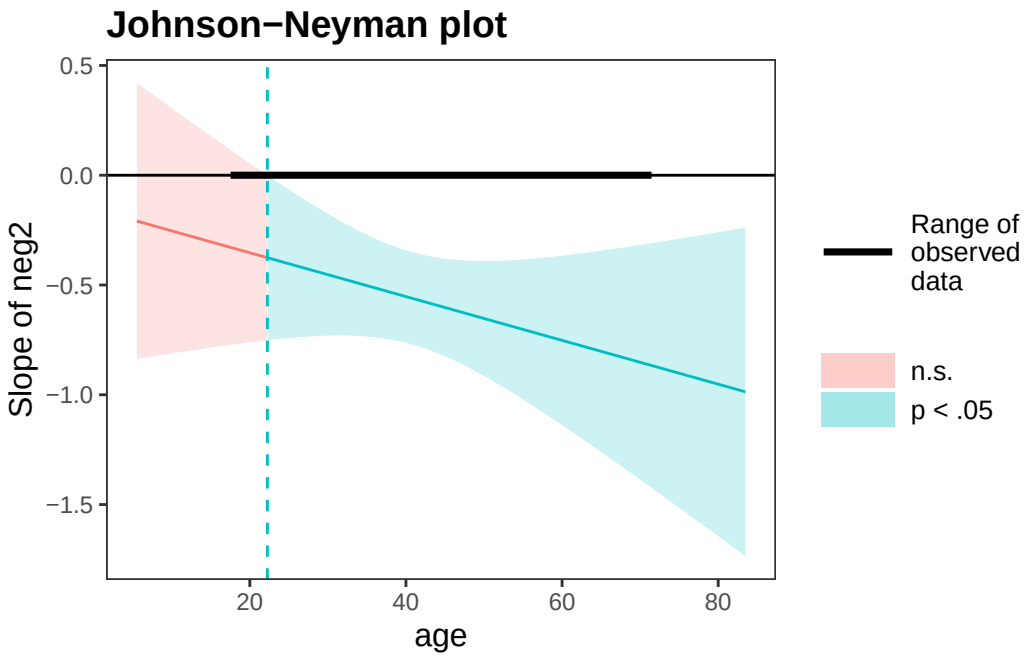

interactions::johnson_neyman(mod2.jn, pred = "neg2", modx = "age",
                             control.fdr = TRUE)
```

```
JOHNSON-NEYMAN INTERVAL

When age is INSIDE the interval [22.25, 120.37], the slope of neg2 is p <
.05.

Note: The range of observed values of age is [18.00, 71.00]

Interval calculated using false discovery rate adjusted t = 2.00
```

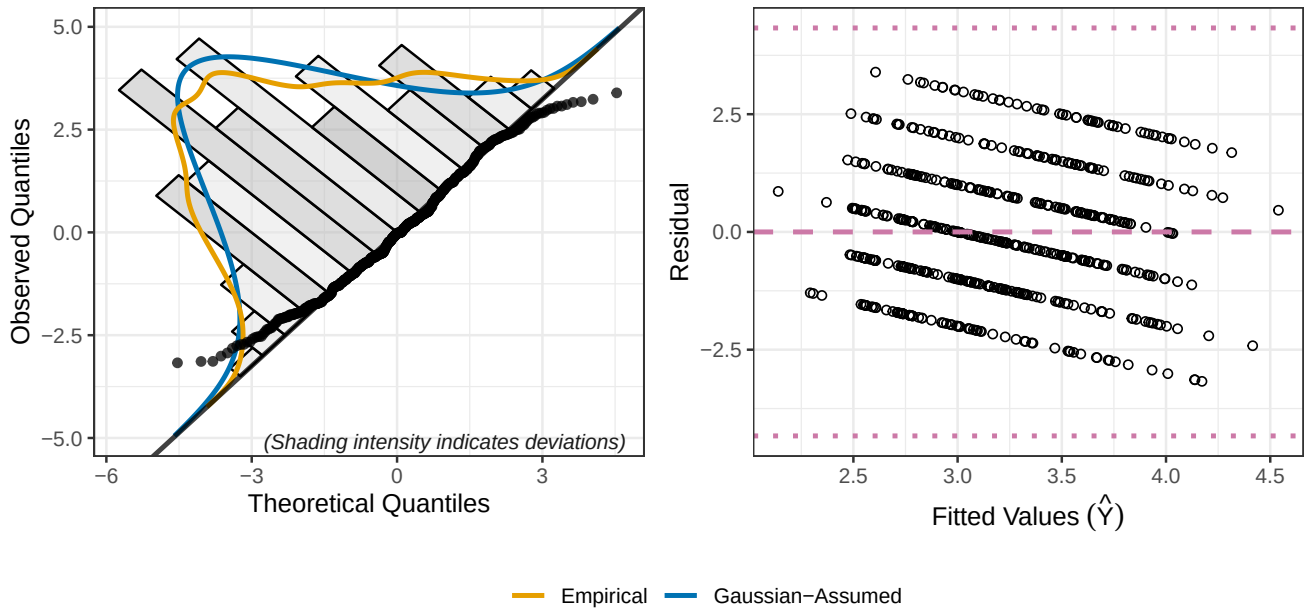

The Johnson-Neyman analysis showed that the framing effect is significant for ages above about 22. However, since the frame × age interaction was not significant, it is not so meaningful to interpret this.

3.3 Preference for Chance Choice

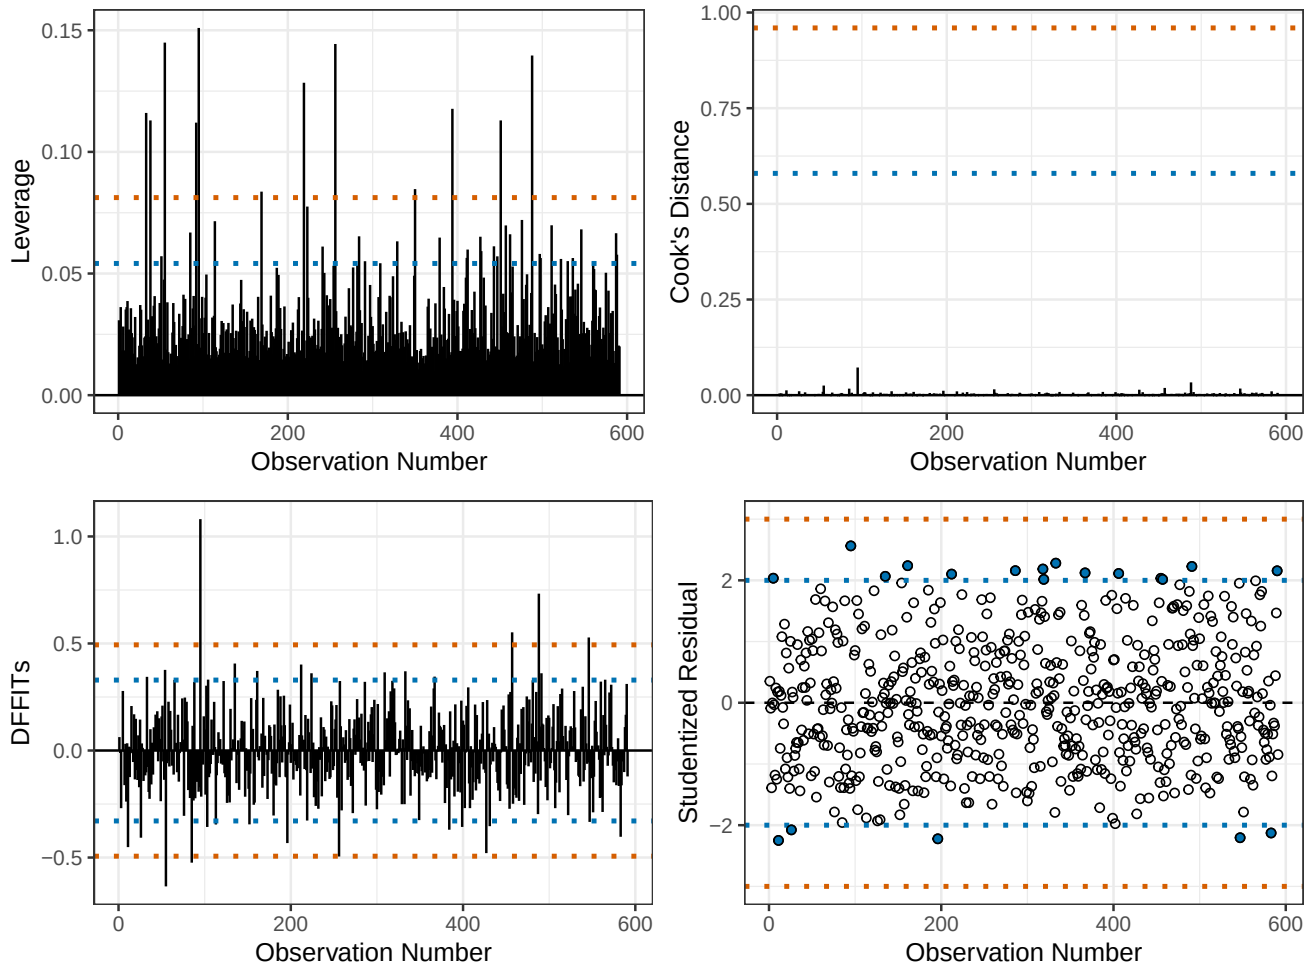

```
mod3 <- lm(pick3 ~ frame3 * age.c + gender + ethnicity + education + politics,
           data = dat)
```

```
plotResiduals(mod3)
```

The residuals fall along parallel bands because responses are integers from 1 to 6. Q-Q plot shows a fair Gaussian distribution.

```
plotInfluence(mod3)
```

Some observations have high leverage, but all Cook's distances are far below the moderate threshold, so no observation is influential.

```
car::vif(mod3)
```

 pos - neg   -1.025 0.306 575  -3.347  0.0009

Results are averaged over the levels of: gender, ethnicity, education, politics
```

The framing effect (negative minus positive) grew from 0.32 points at age 20 to 1.03 points at age 70. It was not significant at age 20 but was significant from age 30 onward.

```r
dat <- dat |>
  mutate(neg3 = as.numeric(frame3 == "neg"))

mod3.jn <- lm(pick3 ~ neg3 * age + gender + ethnicity + education + politics,
              data = dat)

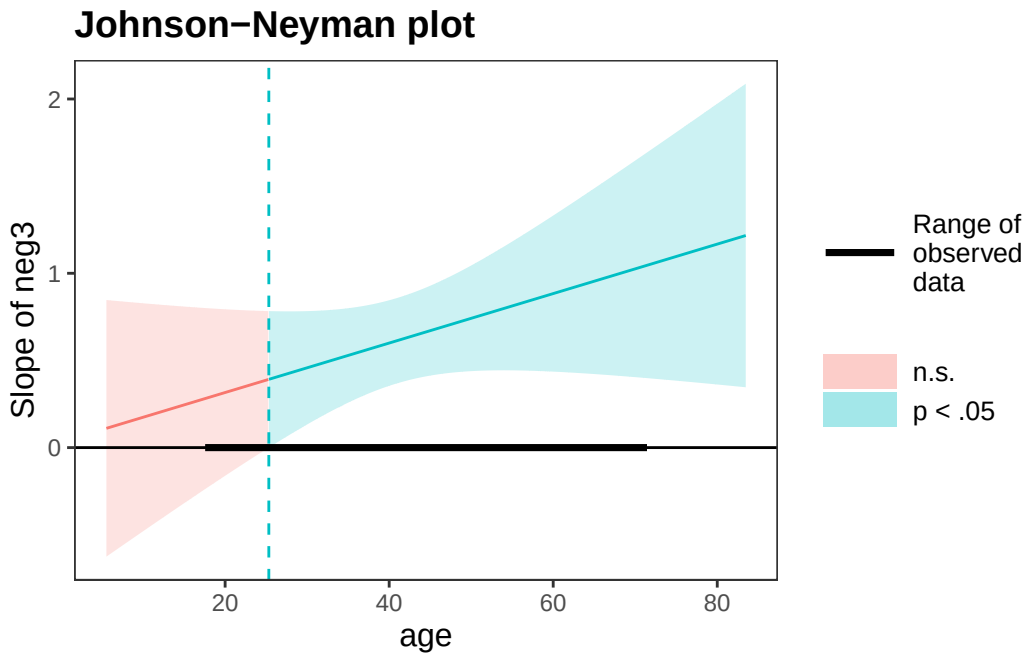

interactions::johnson_neyman(mod3.jn, pred = "neg3", modx = "age",
                             control.fdr = TRUE)
```

```
JOHNSON-NEYMAN INTERVAL

When age is INSIDE the interval [25.33, 151.11], the slope of neg3 is p <
.05.

Note: The range of observed values of age is [18.00, 71.00]

Interval calculated using false discovery rate adjusted t = 2.03
```

The Johnson-Neyman analysis showed that the framing effect is significant for ages between 25.3 and 151.1. This means the effect is significant for participants older than about 25. However, since the frame × age interaction was not significant, I do not interpret 25 as a clear onset age.

4 Discussion

Across all three scenarios, how a choice was worded clearly changed people's responses: the negative frame lowered drug ratings, increased willingness to stop drinking cocoa, and increased preference for the risky option. Whether this framing effect grows with age is less clear. In all three scenarios the interaction pointed in the same direction, with the framing effect larger for older adults, but it was significant only for drug efficacy ($p = 0.042$). In every scenario, the age slope under the positive frame was essentially zero, while the slope under the negative frame was larger and close to significance ($p = 0.099$, 0.056, 0.0498). This pattern is consistent with Xu (2024)'s conclusion that any age-related change is driven by the negative frame, though my evidence for it is weaker.

I did not find a clear onset age. For drug efficacy, the framing effect was significant across the entire observed age range (18–71). For the other two scenarios, the Johnson-Neyman analysis suggested significance after about ag 22–25, but because their interactions were not significant, I do not interpret these as true onset ages. This differs from Xu (2024), who reported onset ages of about 32–34 even though only one of their interactions was significant.

My results may differ from the original study because I analyzed a stricter sample of 592 participants who passed both attention checks, rather than 696.
